Section 1

Introduction to Time Series Analysis

Learning objectives

After completing this tutorials, students should be able to:

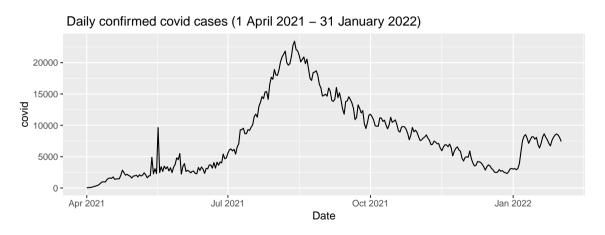

- Understand basic concepts of time series analysis
- Apply statistical models to forecast health outcomes with R
- Evaluate predictive performance of time series models

What is a time series?

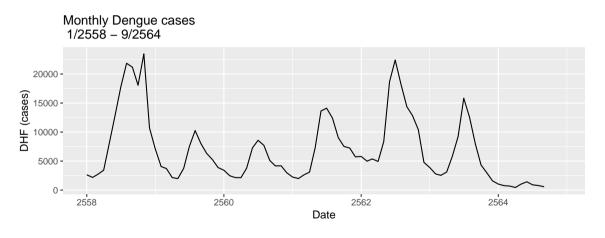

What is a time series?

- A time series is a series of data points indexed (or listed or graphed) in time order.
- Most commonly, a time series is a sequence taken at successive equally spaced points in time.

Section 2

Time Series Visualization

Before working with RStudio, please set working directory to the workshop folder.

Rstudio > Session > Set Working Directory > Choose Directory

Make sure that the workshop directory is displayed in the Files pane (Right-Lower pane of RStudio)

Please install ggplot2 and tidyquant with the following commands:

```
install.packages("ggplot2")
install.packages("tidvguant")
```

Once finished import both packages into R workspace:

```
library(ggplot2)
library(tidyquant)
```

You can load csv data into R workspace with the command read.csv().

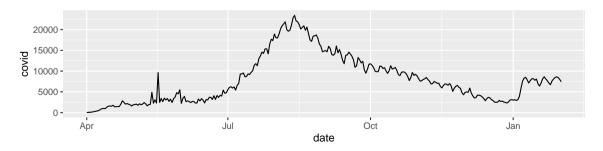

```
covid <- read.csv('data/covidts.csv')
head(covid)</pre>
```

```
##
          date day month year dow week covid

                 5
## 5 2021-04-05
                      4 2021
                                   14
                                       194
                               2
## 6 2021-04-06
                      4 2021
                                   14
                                       250
```

Once loaded, we create a time series plot having date as X and covid as Y.

With ggplot, we use geom_line to create a line plot.

```
# convert date as date variable
covid$date = as.Date(covid$date)
ggplot(covid) +
  geom_line(aes(x=date, y=covid))
```

Now let's create a time series plot of RTI death.

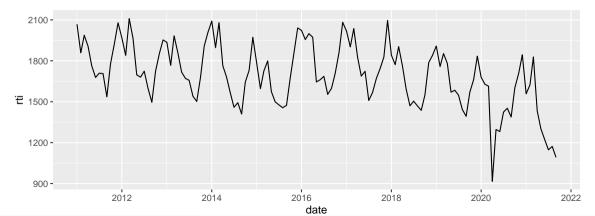

Also, load the data with read.csv() and convert date to date variable.

```
rti <- read.csv("data/rti.csv")
rti$date <- as.Date(rti$date)
head(rti)</pre>
```

```
## date rti year month
## 1 2011-01-01 2068 2554 1
## 2 2011-02-01 1859 2554 2
## 3 2011-03-01 1987 2554 3
## 4 2011-04-01 1907 2554 4
## 5 2011-05-01 1763 2554 5
## 6 2011-06-01 1678 2554 6
```

Plotting the time series plot is also straightforward.

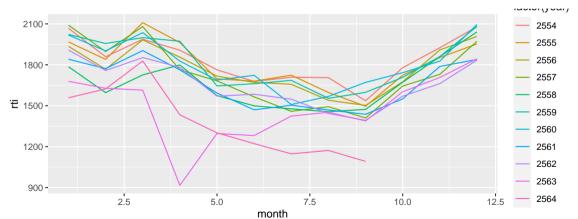

```
ggplot(rti) +
  geom_line(aes(x=date, y=rti))
```

Plotting time series data with R ggplot2

Next, plotting monthly RTI each year is recommended to examine seasonality.

```
ggplot(rti) +
  geom_line(aes(x=month, y=rti, color=factor(year)))
```

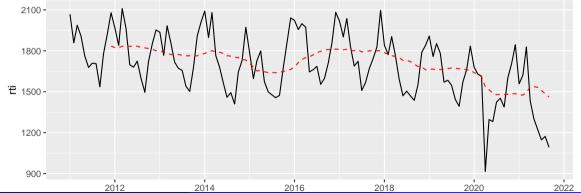

Plotting time series data with R ggplot2

To examine trend pattern, a moving average is recommended.

In this exercise, we use $geom_ma$ of tidyquant package to create the moving average (of 12 months) plot.

```
ggplot(rti) +
  geom_line(aes(x=date, y=rti)) +
  tidyquant::geom_ma(aes(x=date, y=rti), ma_fun=SMA, n=12, color='red', type='l')
```

STL Decomposition

Another way of visualizing time series components is by decomposing them.

Additive: $Y_t = Trend_t + Seasonal_t + Cyclic_t + Others_t$

Multiplicative: $Y_t = Trend_t \times Seasonal_t \times Cyclic_t \times Others_t$

There are methods we used to decompose the time series, e.g. X11, STL.

STL Decomposition

Now we'll use the method called STL decomposition to decompose the RTI death.

Firstly, we have to create a time series object from existing data.

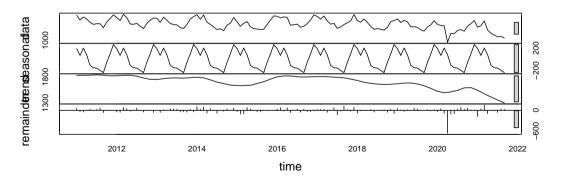

```
ts_rti <- ts(rti$rti, start=c(2011,1), freq=12) # create a time series object ts_rti
```

```

## 2019 1908 1758 1853 1781 1570 1584 1548 1443 1393 1570 1662 1834
```

STL Decomposition

We use the command stl to decompose the time series RTI data.

```
decomposition <- stl(ts_rti, t.window=12, s.window="periodic", robust=TRUE) #
plot(decomposition)</pre>
```

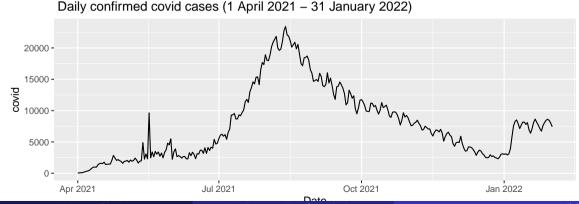

Time series correlation

Most time series data are correlated with themselves.

In statistics, this is called autocorrelation.

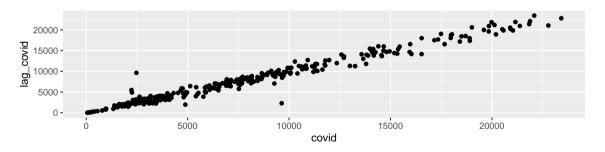

For example, cases tend to be correlated (similar) with others, especially at the nearest time point.

Time series correlation

We could use a scatter plot to visually examine the correlation of Covid-19 cases with its lag (yesterday cases).

```
covid$lag_covid <- lag(covid$covid, 1)
ggplot(covid) +
  geom_point(aes(x=covid, y=lag_covid))</pre>
```

Time series correlation

We could also use the Pearson's correlation coefficient.

```
with(covid, cor(covid, lag_covid, use='complete.obs'))
```

```
## [1] 0.985227
```

The value 0.98 suggested a strong correlation between today Covid cases and yesterday cases.

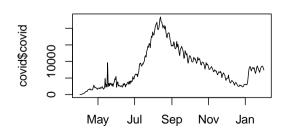

The autocorrelation function (ACF) is essentially a function to determine the Pearson's correlation of a time series data and its previous lag at any time points.

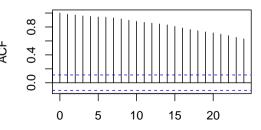

In R, the ACF is called by the acf command.

```
# format subplots having 1 row and 2 columns
par(mfrow=c(1,2))

plot(covid$date, covid$covid, type='l')
acf(covid$covid)
```

Series covid\$covid

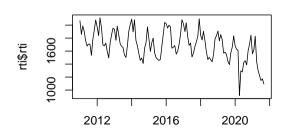

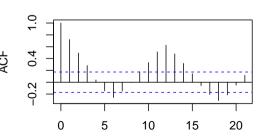

```
# format subplots having 1 row and 2 columns
par(mfrow=c(1,2))

plot(rti$date, rti$rti, type='l')
acf(rti$rti)
```

Series rti\$rti

After examining the ACF, it is obvious that most time series data are correlated with its lag.

However, the ACF cannot exactly determined the correlation with it, say 7th lag, given all other lags.

This is because the correlation with the 7th lag may be confounded with other lags.

Partial Autocorrleation Function (PACF)

The Partial Autocorrelation Function (PACF) also shows the Pearson Correlation Coefficient of the time series and its lags.

It is different from the ACF in that the function is given by all other lag (meaning that there would be no confounding effects from other lags).

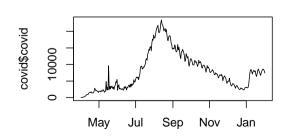

In R, we use the command, pacf.

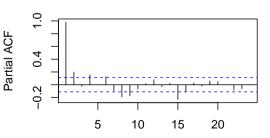

Partial Autocorrelation function (PACF)

```
# format subplots having 1 row and 2 columns
par(mfrow=c(1,2))

plot(covid$date, covid$covid, type='l')
pacf(covid$covid)
```

Series covid\$covid

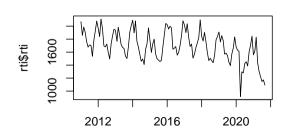

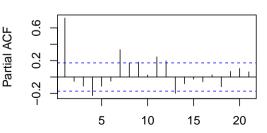

Partial Autocorrelation function (PACF)

```
# format subplots having 1 row and 2 columns
par(mfrow=c(1,2))

plot(rti$date, rti$rti, type='l')
pacf(rti$rti)
```

Series rti\$rti

Stationary

Another important concept in time series analysis is stationary.

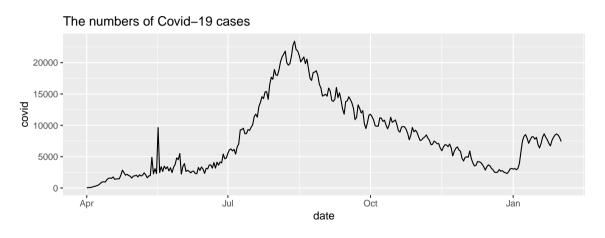

This is because most time series forecasting models require stationary assumptions.

Stationary

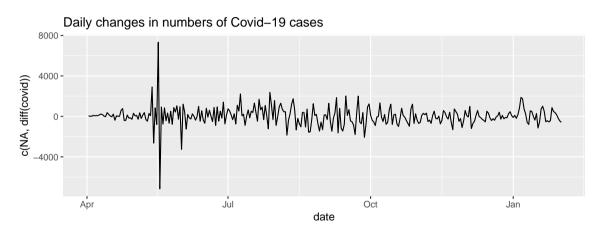

A time series Y is said to be stationary if all of its values y_t do not depend on time t. In other words, the distribution of y_t has constant mean and variance.

Introduction to Time Series Analysis

Stationary?

Stationary?

How to transform non-stationary time series to be stationary

Stationary is characterized by constant mean and variance.

Transformations help to stabilize the variance.

Difference help to stabilize the mean

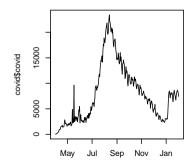

Transformations

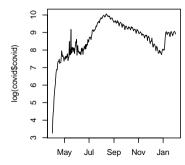

Variance could be stabilized by taking:

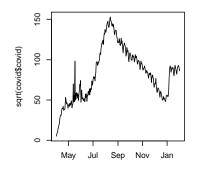

- (Natural) Logarithm (log)
- Squared root (sqrt)

Transformations

```
par(mfrow=c(1,3))
plot(covid$date, covid$covid, type='l')
plot(covid$date, log(covid$covid), type='l')
plot(covid$date, sqrt(covid$covid), type='l')
```

covid@date

Transformations

We found that taking natural logarithm on Covid cases mostly stabilize the variance.

```
covid$log_covid <- log(covid$covid)
head(covid[, c('date', 'covid', 'log_covid')])</pre>
```

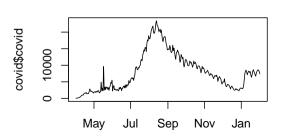

```
##
          date covid log covid
  1 2021-04-01
                  26
                     3.258097
  2 2021-04-02 58 4.060443
  3 2021-04-03
                 84 4.430817
  4 2021-04-04
                96 4.564348
  5 2021-04-05
                 194
                     5.267858
  6 2021-04-06
                 250
                     5.521461
```

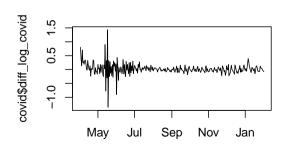

Differencing

Difference helps stabilize the mean.

In R, we could use the command diff() (plus NA offset at the first index).

```
covid$diff_log_covid <- c(NA, diff(covid$log_covid))
par(mfrow=c(1,2))
plot(covid$date, covid$covid, type='1')
plot(covid$date, covid$diff_log_covid, type='1')</pre>
```

Section 3

Time Series Regression

Linear regression applied to time series data

$$y_t = \beta_0 + \beta_1 x_{1,t} + \beta_2 x_{2,t} + \dots + \beta_n x_{n,t} + \epsilon_t$$

- y_t is the value of a time series Y we want to predict.
- $x_{n,t}$ is the *n* predictor, which could be any other values from other series, or the time *t* itself.
- \bullet ϵ_t is the error term called the white noise, where

$$\epsilon_t \sim \mathcal{N}(\mu, \sigma^2)$$

Linear regresssion in R

In R, linear regression is fitted with the command lm().

The formula of the command is $Im(y \sim X, data)$, where y is the predicted variable and X are the predictors.

```
fit <- lm(rti ~ year + factor(month), data = rti)
summary(fit)

##

## Call:
## lm(formula = rti ~ year + factor(month), data = rti)
##

## Residuals:
## Min 1Q Median 3Q Max
## -680.54 -58.91 16.22 64.04 249.09
##

## Confficients:</pre>
```

The most common application of time series regression is to predict time series based on another series.

For example, if we wish to predict the number of COPD visits based on asthma visits.

```
ncd <- read.csv('data/aci_month.csv')
ncd$date <- as.Date(ncd$date)
ncd</pre>
```

```

                                        9 2014
```

We could create the predicted variable: the number of COPD visits in the next month.

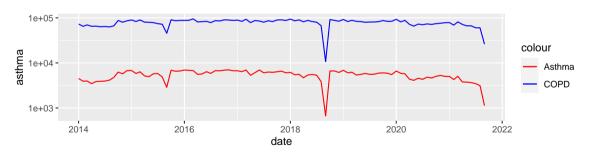

We do this by taking leading of time series.

#:	#		date	${\tt asthma}$	copd	ihd	${\tt month}$	year	copd_nextmonth

			Kritchavat Ploddi			ntroductio	n to Time Se	ries Analys	212

Introduction to Time Series Analysis

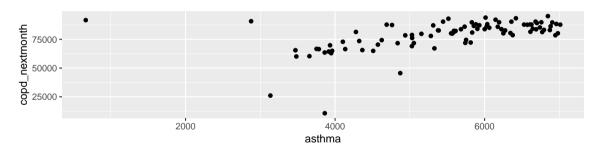

Before we begin, we should plot both time series (asthma and COPD) to see whether there are patterns associated with both series.

```
ggplot(ncd) +
  geom_line(aes(x=date, y=asthma, color='Asthma')) +
  geom_line(aes(x=date, y=copd, color='COPD')) +
  scale_colour_manual(breaks=c("Asthma", "COPD"), values=c("red", "blue")) +
  scale_y_log10()
```

To identify any linear relationship between asthma and COPD, we could use the scatter plot.

```
ggplot(ncd) +
  geom_point(aes(x=asthma, y=copd_nextmonth))
```

It is clearly seen that there is linear relationship between both series.

Now we could fit the linear regression between asthma and COPD.

```
lm_copd_asthma <- lm(copd_nextmonth ~ asthma, data=ncd)</pre>
summary(lm_copd_asthma)
##
## Call:
## lm(formula = copd nextmonth ~ asthma, data = ncd)
##
## Residuals:
     Min
             10 Median
                                 Max
## -58397 -4282
                   683 3990 42137
## Coefficients:
               Estimate Std. Error t value Pr(>|t|)
## (Intercept) 4.551e+04 5.546e+03 8.206 1.53e-12 ***
              6.109e+00 9.924e-01 6.155 2.04e-08 ***
## asthma
## Signif. codes: 0 '***' 0.001 '**' 0.05 '.' 0.1 ' ' 1
## Residual standard error: 11110 on 90 degrees of freedom
    (1 observation deleted due to missingness)
## Multiple R-squared: 0.2963, Adjusted R-squared: 0.2884
## F-statistic: 37.89 on 1 and 90 DF, p-value: 2.044e-08
```

For the prediction task, we are interested in the coefficients (not the standard error or p-value).

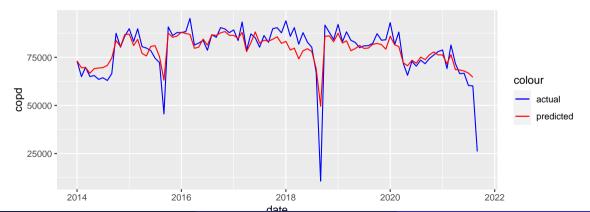

```
## (Intercept) asthma
## 45510.918092 6.108965
```

$$E[COPD] = 45510.918092 + 6.108965 \times Asthma$$

Note the we use E[...], which is denoted as the expected number of ..., in other words, we are predicting the mean of COPD visits next month.

We could use predict function to predict COPD cases using the fitted model.

```
ncd$predicted_copd <- c(predict(lm_copd_asthma), NA)
ggplot(ncd) +
    geom_line(aes(x=date, y=copd, color='actual')) +
    geom_line(aes(x=date, y=predicted_copd, color='predicted')) +
    scale_colour_manual(breaks=c("actual", "predicted"), values=c("blue", "red"))</pre>
```

However, it is assumed that we have already know the actual asthma visits, in order to forecast the COPD visits in the future.

If it is not the case, we have to forecast the COPD visits based on its trend and seasonality.

Assuming that the trend is continuing downward further from 2019.

Firstly, we split the training data only on and after 2019.

```
ncd2019 <- ncd[ncd$year >= 2019, ]
ncd2019
```

##		date	asthma	copd	ihd	${\tt month}$	year	copd_nextmonth	<pre>predicted_copd</pre>

Forecasting PM 2.5

```
lm_pm <- lm(PM25 ~ DATETIMEDATA+hour+dow, pm)
pm$fit <- lm_pm$fit
plot(pm$DATETIMEDATA, pm$PM25, type='1')
lines(pm$DATETIMEDATA, pm$fit, col='red')</pre>
```

In this tutorial, we will predict Dengue cases, based on rainfall data.

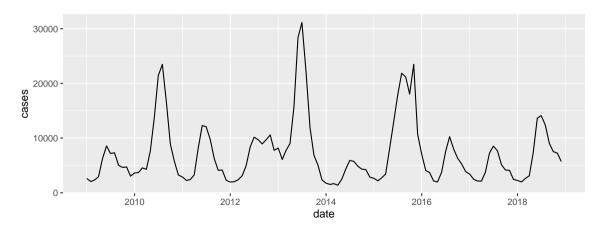

Firstly, loaded the data containing dengue cases and rainfall data.

```
dhfrain <- read.csv('data/dhfrain.csv')</pre>
dhfrain$date <- as.Date(dhfrain$date)</pre>
head(dhfrain)
           date year month cases mean rain max rain year from last epidemic

                                               157.1
```

read the data

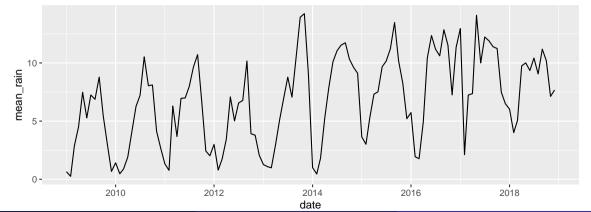

We visualize time series of monthly dengue cases.

```
ggplot(dhfrain) + geom_line(aes(x=date, y=cases))
```

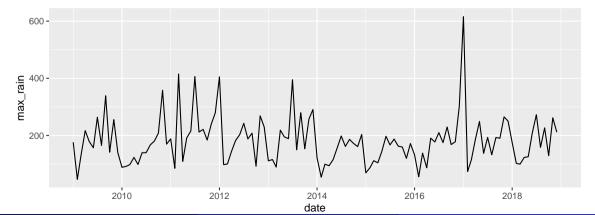

Next, mean monthly rainfall is shown.

```
ggplot(dhfrain) +
  geom_line(aes(x=date, y=mean_rain))
```

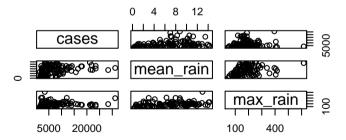

Next, visualizing max rainfall each month

```
ggplot(dhfrain) +
  geom_line(aes(x=date, y=max_rain))
```

We could also examine the relationship between DHF cases and rainfalls.

```
pairs(dhfrain[, c('cases', 'mean_rain', 'max_rain')])
```

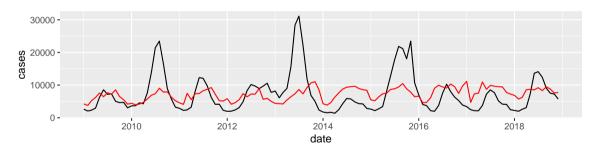

Now, use Im() to fit linear regression.

Firstly, having only rainfall parameters as predictors

```
model dhfrain 1 <- lm(cases ~ max rain+mean rain, dhfrain)
summary(model dhfrain 1)
## Call:
## lm(formula = cases ~ max rain + mean rain, data = dhfrain)
##
## Residuals:
             10 Median
     Min
                                Max
   -7730 -3633 -1654 1984 22483
##
## Coefficients:
              Estimate Std. Error t value Pr(>|t|)
## (Intercept) 3549.278 1349.418 2.630 0.00968 **
## max rain
                 2.035
                           6.608 0.308 0.75861
## mean rain 489.410
                         146.535 3.340 0.00113 **
## Signif. codes: 0 '***' 0.001 '**' 0.05 '.' 0.1 ' ' 1
## Residual standard error: 5655 on 117 degrees of freedom
## Multiple R-squared: 0.1057, Adjusted R-squared: 0.09043
## F-statistic: 6.916 on 2 and 117 DF, p-value: 0.00145
```

Use fitted model to produce fitted data.

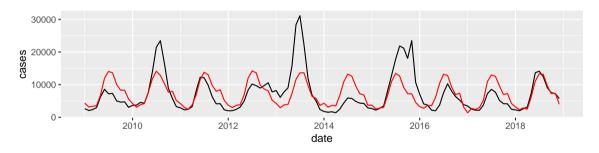

```
dhfrain$fit_dhfrain_1 <- predict(model_dhfrain_1)
ggplot(dhfrain) + geom_line(aes(x=date, y=cases)) + geom_line(aes(x=date, y=fit_dhfrain_1), col='red')</pre>
```

It is clearly seen that this forecast isn't adequate.

Next, we could add month-of-the-year to capture seasonal pattern of the disease.

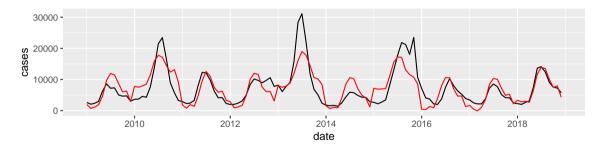

```
model_dhfrain_2 <- lm(cases ~ max_rain+mean_rain+factor(month), dhfrain)
dhfrain$fit_dhfrain_2 <- predict(model_dhfrain_2)
ggplot(dhfrain) + geom_line(aes(x=date, y=cases)) + geom_line(aes(x=date, y=fit_dhfrain_2), col='red')</pre>
```

From this plot, it is clear that adding months improve the forecast but still not capture cyclical pattern.

Next, we use the number of years from last epidemic as proxy indicator for the cyclical pattern

```
model_dhfrain_3 <- lm(cases - max_rain+mean_rain+factor(month)+factor(year_from_last_epidemic), dhfrain)
dhfrain$fit_dhfrain_3 <- predict(model_dhfrain_3)
ggplot(dhfrain) + geom_line(aes(x=date, y=cases)) + geom_line(aes(x=date, y=fit_dhfrain_3), col='red')</pre>
```

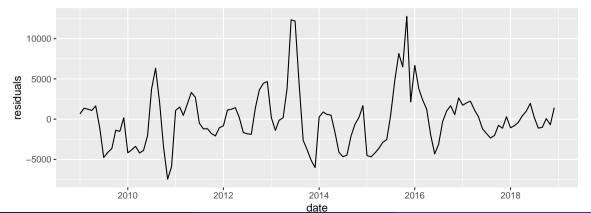

Including the number of years partially capture cyclical pattern.

Now, we should diagnose if the model violate linear regression assumptions.

We calculate residuals, which is unlikely normally distributed.

ggplot(dhfrain) + geom line(aes(x=date, v=residuals))

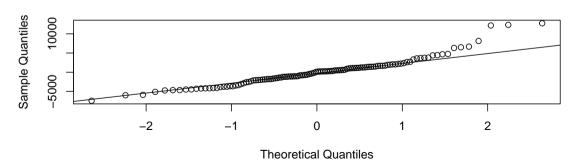

```
dhfrain$residuals <- model_dhfrain_3$residuals
```

Q-Q plot also suggest that the normality assumption is violated.

```
qqnorm(dhfrain$residuals)
qqline(dhfrain$residuals)
```

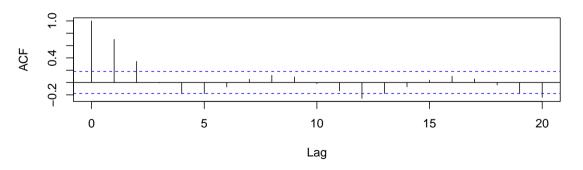

Normal Q-Q Plot

ACF plot reveals autocorrelation at lag 1 and 2. Thereby independence is also violated.

acf(dhfrain\$residuals)

Series dhfrain\$residuals

Final remarks:

- Linear regression is a great method to forecast, especially with incorporating external information.
- However, most of the time series data violate linear regression assumption so that there
 would be some information that didn't be captured by the model.
- The are several methods addressing this problems. The most common ways to handle this
 is to also predict the residuals themselves with other methods, such as ARIMA.
